Microcystins accumulate in aquatic organisms and can be transferred to higher trophic levels, eventually affecting vector animals and consumers. We examined three levels of an aquatic food chain (*Microcystis aeruginosa*, *Daphnia magna* and *Macrobrachium rosenbergii*) to identify the transfer efficiency and risk of microcystin on prawns. Samples were analysed using ultra performance liquid chromatography-mass spectrometry (MS)/MS and microcystin-LR (MC-LR) distributions in prawn tissues were studied. The results showed that prawns accumulate MC-LR both directly from *M. aeruginosa* and indirectly through *D. magna* which was pre-exposed to *M. aeruginosa*. MC-LR was detected in the gills, digestive tracts and hepatopancreas of the prawns 2 h. after exposure. MC-LR accumulated in prawns to 0.49 +/- 0.04 μg g⁻¹ dry weight in hepatopancreas within 24 h, while it was not detected in muscle samples, and rarely appeared in blood samples in such a short period. Although MC-LR was not detected in muscle, the head including hepatopancreas of the prawns accumulated troublesome amounts of MC-LR. These results demonstrate that microcystis blooms in prawn farming potentially pose a risk to human consumers, although prawns may be exposed to the bloom for a very short time, hence regular monitoring of blue green algae population is recommended.
